Centre for Health Economics ISSN 1833-1173 ISBN 1 921187 82 4 The Multi Instrument Comparison (MIC) survey is a project funded by a National Health and Medical Research Council (NHMRC) project grant (ID 1006334) 'A cross national comparison of eight generic quality of life instruments'. (Since its inception, three additional instruments have been added).

The Norwegian arm was facilitated by a grant from the University of Tromso.

The German arm of the study was funded by **Deutsches Krebsforschungszentrum** (DKFZ), the German Cancer Research Centre in Heidelberg and conducted with the **Institute for Innovation & Valuation in Health Care** in Weisbaden.

Chief Investigators on the project are:

Professor Jeff Richardson (Monash University, Australia) Professor Robert Cummins (Deakin University, Australia) Professor Robert Kaplan (University of California Los Angeles, USA) Professor Jan Abel Olsen (University of Tromso, Norway) Professor Michael Schlander (University of Heidelberg, Germany) Professor Joanna Coast (University of Birmingham, England)

Upon completion of the project all data will be made publicly available.

ABSTRACT

The Multi Instrument Comparison (MIC) project is the largest comparative study of health and wellbeing instruments undertaken worldwide. To date 8022 individuals [from six countries] have completed twelve instruments relating to their health or wellbeing. Data were collected from a representative healthy cohort and from patients in seven clinical areas in each of six countries.

This and subsequent country-specific research papers report data related to the project study questions. They do not seek to interpret data or comment on the study questions. This will be the subject of later publications.

Countries, diseases and questionnaires included in the MIC are summarised in Boxes 1 to 4 below. The background study questions questionnaires and utility weights used are outlined in detail in MIC Paper 1, Background, Questions, Instruments (Richardson, Iezzi et al. 2012). Choice of weights is also discussed in Section 8.

Total sample (after editing)		Health state (after editing	Health state (after editing)		
Australia	1430	Arthritis	929		
UK	1356	Asthma	856

Cross-national comparison of twelve quality of life instruments MIC Paper 6: Norway

1 Introduction

Objectives

The background and objectives of the MIC project are described in MIC Paper 1 (Richardson, lezzi et al. 2012). In sum, the project is a response to the evidence that different MAU instruments produce different values for 'utility' and (despite the common label 'utility') measure different constructs. The principle objectives of the project are, firstly, to document the differences in the values produced by the instruments for different groups of patients in different countries; and, secondly, to determine what the different instruments measure – which dimensions of wellbeing explain variation in instrument scores.

To achieve these objectives we sought respondents with a diverse range of health states and, specifically, health states associated with major disease areas. This implies that the total sample is not representative of the population as the focus of the study is the relationships between instruments in different health states and not the wellbeing of the overall population. Despite this, comparisons may be made with population or other instrument norms. 'Patients' complete a disease-specific questionnaire for which there are norms and the non-patient sample may be weighted to correct for any mismatch between them and independently obtained norms if population values are needed.

The primary objectives relate to the content and validity of existing instruments, ie those which are currently used for cost utility analysis (CUA). While the investigation of the psychometric properties of the instruments are a further area of inquiry the main research, including results reported in this paper, use unadjusted MAU instruments irrespective of their reliability as indicated by the present data. The instruments are currently used irrespective of their properties.

The administration of the MIC survey is illustrated in Figure 1. A survey company, CINT, invited individuals on their database to participate. A person accepting this invitation was first asked to complete the three subjective wellbeing questions: the Personal Wellbeing Index (PWI), the Integrated Household Survey (IHS) and the Satisfaction with Life Survey (SWLS). These questions were administered immediately as they seek to measure 'affect' – a person's 'undigested' feelings. Asking the questions after 'priming' respondents with questions about their health (do you have one of the eight diseases of interest?) would potentially create biased responses.

After completion of these questions the respondent was asked the following question: 'Have you got a current diagnosis of any of the following health problems? Please choose the most serious illness you have.'

Those nominating one of the survey diseases proceeded with the survey if and only if the quota – the target number of respondents – had not been reached. To confirm the patient's status the first question was a repetition of the question above. Patients then completed the core questionnaire which was administered to all respondents within the quota. This was followed by the disease-specific questionnaire which applied to their particular disease.

Those who did not report a disease were questioned about their age, gender and education. Additionally they were asked to indicate their overall health on a visual analogue scale (VAS) where 'Zero is the least desirable state of health you could imagine and 100 is the best possible health (physical, mental and social).' The individual was invited to proceed to the core questions only if their VAS score exceeded 70 and their age, gender and education quota had not been filled. The VAS criterion was included to ensure that the 'healthy public' excluded those whose self rating was very poor. The web-based procedures employed here attract a disproportionate number of distressed respondents (in Australia) and the procedure was adopted to reduce this effect and increase the sample size of respondents in good health. The number 70 was selected judgementally to achieve this goal but to permit variation in 'normal health'.

Figure 1 Administration of the MIC online questionnaires

Edit procedures

A. Public group

Edit 1: Any responses that were done in less than 15 minutes were eliminated. The survey median completion time was 26 mins (range 10.8- 108.1 mins). Times between 15-20 mins were marked to inspect at the final edit.

Edit 2: In round two, inclusion into the survey was predicated on a VAS rating of 70 and above.

Edit 3: Respondents were removed from the dataset if they indicated that they suffered from any of the disease states (asthma, cancer, depression, diabetes, hearing loss, osteoarthritis or heart disease).

Edit 4: The EQ-5D mobility question was duplicated in the survey. Anyone with a response that varied by more than +/-1 difference was eliminated. Those differing by only +/- 1 were examined with other criteria to determine their eligibility.

Edit 5: EQ5D question 4 (pain) and AQoL-8D question 22 (pain) answers were compared. Anyone with 2 response levels difference was eliminated.

Table 1a Public edits

Deleted Edit 1	27
Edit 2	0
Edit 3	1
Edit 4	1
Edit 5	2
Total after edits	288 (68 deleted)

(275 agreed to a 12 month followup)

B. Disease group

Edit 1: Any response that was completed in less than 15 minutes was eliminated. The survey median completion time was 27 minutes (range 6.6-199.3 minutes). Times between 15-20 minutes were marked to inspect at the final edit.

Edit 2: The EQ-5D mobility question was duplicated in the survey. Anyone with the two responses that varied by more than +/- 1 difference was eliminated. Those differing by only +/- 1 were examined with other criteria to determine their eligibility.

Edit 3: The SF-36 question 1 and question concerning own health were identical. Those with responses greater than +/- 1 were eliminated. Those without identical answers but within +/- 1 were earmarked.

Edit 4 and 5 were not possible as the QWB was not included.

Edit 6: EQ-5D question 4 (pain) and AQoL-8D question 22 (pain) were very similar. Those with two response level differences were eliminated.

Edit 7: The number of inconsistencies from edits 2, 3, 4, 5, 6 was coded. Anyone with 2 or more inconsistencies and a time less than 25 minutes was eliminated.

Edit 8: Anyone with 3 inconsistencies from edits 2, 3, 4, 5, 6 was eliminated.

The effect of these procedures on Norwegian respondents with self-reported disease is shown in the following table.

No completed	1099
Deletions due to duplicated ID	108
Deleted Edit 1	52
Edit 2	14
Edit 3	29
Edit 6	7
Edit 7	0
Edit 8	0
Total after edits	889 (210 deleted)

Table 1b Disease edits

Utility weights

Utility weights for all instruments are not available for all countries. Box 4 reports the weights used in the initial analysis with the project. In principle the use of alternative weighs for different countries may alter results. This is discussed further in Section 8 which presents a comparison of US and UK weights for the EQ-5D data from the MIC project. It does not suggest that the explanatory power of the EQ-5D could alter with a choice between these weights.

2 Respondent characteristics

The healthy public

After conclusion of the edit procedures outlined above 1177 respondents were retained, 889 patients' and 288 representing the 'healthy public'. Table 2.1 shows the distribution of respondents by age and gender compared with the Australian norm.

The highest level of education of the public respondents by gender is reported in Table 2.2

Patient samples

889 patient surveys were retained. The focus of the study is upon the comparison of instruments and the purpose of the patient samples was primarily to maximise the diversity of health states in the sample. Consequently, no age-gender quotas were used. Table 2.3 disaggregates respondents by age, gender and disease group. It indicates that the overall sample is highly skewed with respect to age.

A	Norwa	Tatal	
Age group	Male	Female	Total

3 Summary statistics

Mean values

Summary statistics for the instruments are reported in Tables 3.1 and 3.2. MAU instruments purport to measure the same construct – utility. Consequently, direct comparison of their scores is appropriate. Other instruments may not be directly compared. The PWI, SWLS and IHS all measure facets of subjective wellbeing (SWB). However, they do not purport to measure the same construct and their correlation reflects this (see Table 4.4).

Differences between patient groups are not the principle focus of the present report.

Frequency distributions for each of the instruments are reported in Appendices 1 and 2.

	EQ-5D ⁽¹⁾	HUI3	SF-6D	15D	AQoL-8D ⁽³⁾

Table 3.2 Summary statistics for the MAU instruments (Total n=1177)

Internal reliability

A test of scale reliability was carried out with public data using the Cronbach's alpha (Cronbach 1951). This determines the internal consistency or average correlation of items in a survey instrument. The reliability of a scale can vary depending on the sample that it is used with. Table 3.3 reports the alpha coefficient. If this is above 0.7, the scale can be considered reliable with the sample (Pallant 2010). The result shows that all of the scales pass this test except for the SF-36, IHS and HUI 3.

Instrument	N of items	Cronbach's Alpha
AQoL-8D	35	0.95
HUI3	8	0.58*
EQ-5D	5	0.73
15D	15	0.84
SF-36	36	0.48*
IHS	4	0.38*
SWLS	5	0.94
PWI	9	0.91

Table 3.3 Reliability of instruments

* These values are below those generally accepted as indicating the reliability of a scale.

Figure 3.1 Mean of MAU instruments (Total n=1177)

4 Correlation

Validation tests draw heavily upon correlation. In particular, convergent validity is established if an instrument correlates as predicted with other instruments or criteria scores which are believed to correlate with the construct. Higher correlation justifies greater confidence in overall validity. The MIC project collected several types of data to test convergent validity. These were:

- 1. Other MAU scores. As each MAU instrument is believed to reflect 'utility', the instruments can 'cross validate'. Confidence in one MAU instrument increases when it correlates with the other MAU instruments.
- Subjective Wellbeing (SWB) score. Utility is commonly equated with SWB. This is not strictly correct as people's preferences do not always maximise happiness (Richardson, Maxwell et al. 2012). However the two constructs are undoubtedly related and high correlation with SWB is independently important if MAU instruments are to influence policy decisions. The three instruments used here – PWI, SWLS and IHS – are outlined in MIC Research Paper 1 (Richardson, lezzi et al. 2012).
- 3. Self TTO. The concept and measurement of self TTO are also explained in MIC Research Paper 1. It is conceptually the same as a conventional TTO except that the health state evaluated is not 'external' as described to the respondent, but the respondent's own health state. The relationship between self and conventional TTO is the subject of ongoing research.
- 4. Disease-specific QoL instruments. These are not utilised in the current report.

The Pearson correlation between MAU instruments, between MAU and non-MAU instruments and between non-MAU instruments are reported in Tables 4.1-4.6 and Fig 4.1-4.7. The Pearson correlation indicates the extent to which changes in one variable correspond with changes in another. It does not indicate that two variables are the same or even the same order of magnitude.

The better measure of this is the intraclass correlation (ICC). This is reported in Table 4.6 and Figure 4.7. The difference is parenthesised by the relative score for the 15D. This has the highest average Pearson correlation but (reflecting significant differences in its predicted utility scores) it has the lowest ICC.

Overall the ICC reflects a poorer correspondence between instruments than the Pearson correlation. The imperfect correspondence is also illustrated by the use of R^2 coefficients in Figure 4.3 rather than Pearson correlation coefficients ($R^2 = \rho^2$). This is because a complete explanation of variation would imply $R^2 = 1$. The extent to which the R^2 falls short of 1.00 indicates the extent to which variance is explained by some unknown variable or variables.

Correlation with non-MAU instruments are shown in Table 4.3a and b and Figures 4.2–4.6. The low correlation between measures of utility and PWI and SWLS is in need of explanation. While preferences may differ from subjective wellbeing (SWB) their correlation might be expected to be higher than observed here.

Figure 4.7 Average Intra Class Correlation with other MAU instruments (Total n=1177)

5 Linear relationships

The MAU instruments were designed for use in cost utility analyses (CUA) in which, typically, utilities are measured before and after an intervention. This implies that it is the change in measured utilities, not their absolute values, which are important for validity. The comparative performance of the different instruments in this respect is not identified by either Pearson or intraclass correlations. It is however, easily measured with linear regression.

If instrument X is the criterion variable then the validity of the change predicted by instrument Y may be tested by the magnitude of the b coefficient in the linear relationship Y = a + bX. The absence of bias implies that b = 1.00. In the present case there is no criterion variable. However as with correlation, 'cross validation' may increase confidence: confidence rises if the b coefficients of an instrument are close to 1.00 in the linear relationships with the other MAU instruments. A technical problem which arises with this test is that, because both measured variables in the comparison are subject to error, the parameters will be sensitive to the choice of dependent and independent variable in OLS regressions. One solution to the problem is to use Geometric Mean Squares (GMS) regression. This is obtained by regressing Y on X then X on Y and deriving parameters from the geometric mean of the two regressions. Results are independent of the choice of dependent and independent variable. This technique was used in the present study.

Figure 5.1 reproduces 10 pairwise GMS regressions, their scattergrams and the two GMS equations (Y on X; X on Y) using public data. Figure 5.2 gives the same results using the total sample.

Table 5.2 employs the results for the total sample to derive an average deviation away from b = 1 for each of the 4 regressions which include a particular MAUI. Depending upon the choice of left and right hand scale variable, 'b' may be greater than or less than 1.00. For consistency, the GMS regression was selected where b > 1. Thus from Figure 5.2 the linear relationship between the EQ-5D and HUI 3 for all respondents may be expressed either as (1) EQ-5D = 0.057 + 0.935 HUI 3 or as (2) HUI 3 = -0.061 + 1.069 EQ-5D. Table 5.1 indicates the instruments on the left and right of the selected equation using abbreviations (eg H = 1.069 EQ). From the bottom row in Table 5.1 the deviation for the MAUI vary from 31.3 percent (AQoL-8D) to 67.0 percent (15D). If these linear relationships were generally true (and not just for the present sample) the results would imply that the choice of AQoL-8D rather than one of the other six instruments would result in a 67.0 percent discrepancy.

Table 5.2 presents a different comparison using b coefficients. The bottom left of the table reports the b coefficients when instrument B is the left hand variable in the regression and instrument A is the right hand variable. The first figure is derived from the public regression and the second figure from the total sample. (Thus, in the public regression EQ-5D = 0.303 + 1.324 HUI 3 (Figure 5.1), the reported b coefficient is 1.324 rounded to 1.32. The b coefficient for the total sample is 0.935(Figure 5.2.) The difference between these coefficients is given in parentheses in Table 5.2. This is an indicator of the stability of the linear relationships involving an instrument when the severity of the health state changes. Thus, for example between the two samples the average of the 4 coefficients in equations with the EQ-5D as the dependent variable, change by 54 percent.

6 Instrument content (sensitivity)

Each MAU defines a 'construct'. Results in this section seek to identify how clearly related dimensions of health/wellbeing are to the MAU constructs. Conversely the results seek to determine how sensitive the MAU constructs are to the dimensions. The dimensions used in the study are obtained from the SF-36 and AQoL-8D which have been independently shown to have construct validity (Richardson, Elsworth et al. 2011). Additionally, the widely used and validated SWB instruments, the PWI and SWLS are employed as is the yet unvalidated Self TTO. Similar results may be obtained for the IHS.

Ceiling effects: From Table 6.1a ceiling effects differ greatly. In the public sample the maximum score (the 'ceiling') was obtained by 46.8 percent of the EQ-5D and 1.4% of the AQoL-8D . Amongst the 297 respondents with an EQ-5D score of 1.00 the average scores on other instruments varied from 0.86 for SF-6D to 0.97 for 15D.

15D	none	none	none	none	none	none	0.0			
AQoL-8D	.39	.36	.52	.65	.30	65	5.5			

Floor effects: Table 6.1c reveals similarly large differences in floor effects. For example, when EQ-5D < 0.4 its average score is 0.21. HUI 3, SF-6D and AQoL-8D have average scores of 0.32, 0.51, 0.66 and 0.38 respectively. When HUI 3 < 0.4 average values for EQ-5D, HUI 3, SF-6D and AQoL-8D are 0.42, 0.23, 0.54, 0.67 and 0.42 respectively.

Correlation with summary measures: Table 6.2 and Figure 6.1 report the correlation between MAU scores and the physical and psycho-social summary scores derived from the SF-36 and AQoL-8D. In every case the correlation with the AQoL-8D (non-utility) super-dimension is greater than with the SF-36 summary score. In every case correlation with the physical summary score is greater than with the psycho-social summary scale with the exception of AQoL-8D. The Table suggests three groups of instruments. First, EQ-5D, HUI and 15D are relatively very sensitive to physical health (particularly EQ-5D). AQoL-8D is relatively very sensitive to psycho-social health. SF-6D, QWB and AQoL-4D are between these polar cases.

Figure 6.2 Correlation with average summary scores

Summary Physical and Psycho-Social Dimensions (Average SF-36 and AQoL-8D summary scores)

Split half analysis: Table 6.3 reports results from a comparison of two split halves of the full sample. Each MAU was used, in turn, to rank observations on the basis of which they were divided into a top and bottom half. Dimension and SWB scores were calculated for both halves. The table reports the ratio of these scores. Higher ratios indicate greater sensitivity of an instrument to a dimension or SWB.

Key:

GH=general health; PF = physical functioning; RP = role limit physical; BP = bodily pain; VT = vitality; SF = social functioning; RE = role limit emotional; MH = mental health; PCS =physical component summary; MCS = mental component summary; IL = independent living; Hap = happiness; Cop = coping; Rel = relationships; SW = self worth; Pain=pain; Sen=senses; MSD = mental super dimension; PSD = physical super dimension; PWI = Personal Wellbeing Index; SWLS = Satisfaction with Life Survey; TTO = Time- trade-off

Sensitivity to dimensions: Tables 6.4a, 6.4b; 6.5a, 6.5b and Figure 6.3a, 6.3b report beta coefficients from the regression of MAU scores on dimension scores. The coefficients show the change in the MAU score with a one standard deviation change in the dimension score. MAU scores are measured in standard deviations (of the MAU score) to allow comparison of sensitivity. This avoids the confusion of a large standard deviation with instrument sensitivity. Thus, for example, the 15D compresses scores. But this is offset in the calculation of beta coefficients by a correspondingly small standard deviation. A larger beta coefficient suggests greater sensitivity.

Tables 6.4a and 6.5a report results from regressions with a single explanatory variable. Because of its correlation with other explanatory variables (dimensions) interpretation of the beta score is ambiguous. Table 6.3b and 6.4b use multiple regressions to obtain the standardised beta. In principle this means that the beta coefficients represent the effect of the dimension after

standardising for other dimensions in the regression. From the regressions employing the SF-36 dimensions (Table 6.4b) a one sd increase in each dimension would result in a 1sd increase in the EQ-5D (ie Σ_i Beta_i) of which 54 percent would be attributable to physical function and pain – (.21 + .43)/1.0. Mental health would contribute 27 percent and vitality 1 percent. The same increase in the dimension scores would increase AQoL-8D by 1.11 sd (ie Σ_i Beta_i) of which 40.5 percent (Beta = 0.45)would be attributable to mental health, 17 percent to vitality and only 19 percent to pain and physical function. This suggests that in the AQoL-8D the effects of pain and physical function may be largely mediated through psycho-social factors.

The percentage contribution to total change following a one sd increase in every dimension using data from Table 6.5b is shown in the pie charts, Figure 6.4.

Notes

(ns) = not significant

1 Beta coefficients are the change in the dependent variable, measured in standard deviations (of the dependent) when the independent variable changes by one standard deviation (after standardising for other variables in the regression). They allow direct comparison of the importance of independent variables.

2 Direct comparison of the overall fit with the fit of AQoL-8D is invalid as it is an (exponential) function of the dimensions.

7 Pairwise comparison of instruments

The GMS regressions reported earlier were employed to help explain differences between the instruments' content. The residual from the regression of one instrument upon another was correlated with each of the major dimensions and non-MAU instruments. A positive correlation between the residual of Y regressed upon X and a dimension, D or index, I, indicates a greater sensitivity of the instrument Y to dimension D or index I.

Figure 7.1 presents the correlation results from Table 7.1 and 7.2. Table 7.3 summarises the results and therefore the implications of the data for the relative sensitivity of instruments.

A negative correlation implies the greater sensitivity of instrument X. Since regressions were calculated using geometric mean squares the results are independent of the choice of dependent and independent variable.

Results are given in Tables 7.1 and 7.2. The frequency distributions of the residuals are given in Appendix 3. To put the magnitude of the correlation coefficients in perspective, the average correlation between *unstandardised instruments* is 0.75; that is, a correlation between a *residual and a single dimension* of 0.25 is 0.25/0.75 or one third of this magnitude which is quantitatively large.

8 Discussion and Conclusion

MAU instruments were scored for this paper using the algorithms summarised in Box 4. Prima facie the use of weights derived in one country in a second country may appear to invalidate the results. However this is not necessarily true and the issue of utility weights is complex. First there is very significant within country variation in preferences as found in the UK between social and demographic groups (Kind, Hardman et al. 1999). At best, national weights are themselves an average from heterogeneous groups.

The difference between national averages is presently of unknown importance. More significantly the evidence suggests the variance in scores is relatively insensitive to differences in weights. Using pilot data for this project Richardson and Khan (2012) found that 85 percent of the difference between instruments could be explained by unweighted instrument values, leaving little to be explained by differences in weights. As a further test of this, US and UK weights published by the EuroQol group for the EQ-5D have been applied to the present data and the results reported in Figure 8.1. The R² of 0.99 indicates that, overall, conclusions with respect to correlation and sensitivity could not change with the choice of weights. The significant difference in absolute score at the lower end of the scale suggests, prima facie, an error in the UK values. It appears very implausible that when UK citizens assign a score of 0.29, UK citizens would prefer to be dead.

The two figures also indicate that the new five level EQ-5D-5L does not overcome the problem of insensitivity in the region of good health (ceiling effects). The second highest possible UK and US utility scores are 0.906 and 0.888 respectively. This implies that moving 11 and 9 people respectively from the second highest health state to the highest would be equivalent to saving a life and returning a person to full health for the same period of time. Nevertheless some results might vary and the data available from this project could be reweighted with new scoring formula for difference countries.

The major conclusion to be drawn from this report is that, despite a similarity in the mean scores, the instruments are dissimilar with respect to virtually all other criteria used to compare them. Taking account of the fact that MAUI purport to measure the same quantity the correlation between instruments is low, the marginal relationships inconsistent and their relationship with health dimensions is variable. This suggests that, contrary to the impression generated by use of the generic term 'utility', the instruments are measuring different constructs. In effect each MAU instrument employs a different definition of 'health'. The correlation which exists between instruments does not disconfirm this conclusion. Over a wide range of objects the height and weight of people correlate (the coefficient is about 0.81). But this does not demonstrate the existence of a common property (Chan 2003). A further important conclusion is that the evaluation of instruments is complex. Multiple criteria exist for their assessment many of which have not been discussed in this report.
